Introduction

This document is divided into four parts, each focusing on different aspects of financial and actuarial analysis related to life insurance. The analysis includes calculations of present value, net present value, accumulated value, interest rates, survival probabilities, and the evaluation of annuities and life insurance products

Part I: Cash Flows

In this section, we calculate the Present Value (PV), Net Present Value (NPV), Accumulated Value (AV), and interest rates based on a series of positive and negative cash transactions over a timeline. These metrics help in understanding the time value of money and the impact of cash flow timings on the overall financial outcome.

Part II: Life Tables

We import a dataset from mortality.org on Canada and use it to calculate survival probabilities. Life tables are essential tools in actuarial science, providing a detailed view of the mortality rates and survival probabilities across different ages. These tables are used to estimate the expected future lifetime and other mortality-related measures.

Part III: Life Annuities

This section deals with the calculation of the Present Value (PV) and Expected Present Value (EPV) of life annuities. Annuities are financial products that provide regular payments over a specified period, often used for retirement planning. We will define and compute the values of various types of annuities, including immediate and deferred annuities.

Part IV: Life Insurance

In this final section, we explore various life insurance products, calculating premiums, and the Expected Present Value (EPV) of whole life insurance policies. Life insurance is a contract that pays a benefit to beneficiaries upon the insured's death. We will analyze different scenarios to understand the cost and value of life insurance under varying conditions.

Cash Flows

Present Value

Suppose you want to go on a trip 5 years from now. You have expenses of 3000 each year for 4 years (including this year), followed by an expense of 4000 and a final expense of 5000. How much would you have to deposit at this moment in time to cover all of these future payments? Assume a constant interest rate of 2.14% and payments would take place at the beginning of the year.

We have an expense of 3000 from t=0 to t=3, an expense of 4000 at t=4 and 5000 at t=5

Cash flows

```
cash_flows <- c(rep(3000,4), 4000, 5000)
```

Interest Rate

```
i <- 0.0214
```

Discount factor

```
v <- 1 / (1+i)
```

Discount factors

```
discount_factors <- v ^ (0:5)
```

Present value

```
present_val <- sum(cash_flows * discount_factors)
```

```
present_val
```

```
## [1] 19800.98
```

So you would have to make a deposit of 19800.98 at this current time to cover all of these future payments.

Net Present Value (NPV)

You're the head of a lawn mowing company. You want to invest in a new lawn mower than you are confident will generate cash flows of 50 each month for 3 months, followed by 20 for 2 months. The issue is it costs 185 and you're unsure if it will be a profitable investment. To find out if it is a good investment or not, you must calculate the NPV for this investment. Assume the monthly interest rate is 0.6%.

```

# Define the cash flows
# We have a negative cash flow at t=0 of 500, and 5 positive cash flows of 50 from t=1 to t=5

cash_flows <- c(0, rep(50,3), rep(30,2))

# Discount factors
discount_factors <- (1+0.006) ^ - (0:5)

# NPV
npv <- sum(cash_flows * discount_factors) - 185
npv

```

```
## [1] 21.62449
```

Since our NPV is positive, this indicates that this would be an overall gain ie profit.

Accumulated Value

Suppose instead of making those expenses, you chose to put them into a savings account. What would be your new present value, assuming same interest rate. What would be your new accumulated value?

```

# Cash flows
cash_flows <- c(rep(3000,4), 4000, 5000)

# Define the discount function
discount <- function(s, t, i = 0.0214) {
  (1 + i) ^ - (t - s)
}

# Calculate the pv
pv <- sum(cash_flows * discount(0, 0:5))
pv

## [1] 19800.98

# Calculate the value at time 6
av <- sum(cash_flows * discount(6, 0:5))

# Calculate the value at time 6, starting from present_value
pv * discount(6, 0)

## [1] 22483.39

print(av - pv)

## [1] 2682.41

```

As you can see, there would be a difference of \$2682.41 if you saved the money instead of spending it.

Yearly Payments

Your parents want to start saving money for your university costs. Each year of study will set you guys back by about 7500. You're currently 14 (t=0) and will start attending when you are 19 (t=5). Therefore, your parents will make 1 deposit each year for 4 years (t=1 to t=4). Assume you will attend for 4 years (t=5 to

t=22), the constant annual interest rate is 3.14% and each deposit your parents make is equal. Find the amount of the deposit

```
# discount factors
discount_factors <- (1 + 0.0314) ^ - (0:8)

# deposit pattern
deposits <- c(0, rep(1, 4), rep(0, 4))

# university expenses
payments <- c(rep(0, 5), rep(7500, 4))

# Calculate the present value of the deposits
PV_deposit <- sum(deposits * discount_factors)

# Calculate the present value of the payments
PV_payment <- sum(payments * discount_factors)

# Calculate the yearly deposit K in the first 4 years
yearly_deposit <- PV_payment / PV_deposit
yearly_deposit
```

```
## [1] 6627.546
```

So your parents would have to make a deposit of 6627.546 for each of the 4 years to finance your university.

Varying Interest Rates

You want to take out a loan to open a new restaurant. You plan to take 1000 this year and 3000 next year. You plan to repay the money with equal yearly payments for the 10 years after next year (t=2 to t=11). Note this time the interest rate isn't constant but changes over time. For the first 3 years it is 4%, then for the next 3 years it is 4.5%, then for the final 5 years it is 6%. How much will your yearly payments be?

```
# Interest rates
interest <- c(rep(0.04, 3), rep(0.045, 3), rep(0.06, 5))

# Yearly discount factors
yearly_discount_factors <- (1 + interest) ^ (-1)

# Discount factors
discount_factors <- cumprod(c(1, yearly_discount_factors))

# Cash flows for the first two years
cash_flow <- c(1000, 3000)

# Calculate the present value (PV) of the loan
PV_loan <- sum(cash_flow * discount_factors[1:2])

# Calculate the present value (PV) of the repayments
repayment_years <- 2:11
discount_factors_repayments <- discount_factors[repayment_years + 1]
n_payments <- length(discount_factors_repayments)

# Define the yearly payment variable
yearly_payment <- PV_loan / sum(discount_factors_repayments)
```

```

# Create the full cash flow vector with the repayments
cash_flow_full <- c(cash_flow, rep(-yearly_payment, n_payments))

# Calculate the PV of the repayments to check the balance
PV_repayments <- sum(cash_flow_full * discount_factors)

# Display the yearly payment and the PV balance check
yearly_payment

## [1] 515.2757
PV_repayments

```

```
## [1] -1.705303e-13
```

Our PV is ~0, meaning the PV of the future payments and PV of your loans are equal, hence the yearly payments would be 515.2757

Yearly to Monthly Interest Rate

You plan to take out a 100,000 loan with a yearly interest rate of 2.88%. You want to pay back this loan with fixed monthly payments over the next 15 years. Find how much these monthly payments will be.

```

#number of payments
number_payments <- 12*15

#yearly interest rate
i <- 0.0288

#monthly interest rate

monthly_interest <- (1+i)^(1/12)-1

# Define the discount factors
discount_factors <- (1 + monthly_interest) ^ - (1:number_payments)

# Define the payment pattern
payments <- rep(1, number_payments)

# Calculate the monthly loan payment K
K <- 100000 / sum(payments * discount_factors)
K

```

```
## [1] 683.0401
```

These monthly payments will be 683.0401

Life Tables

```

life_table <- read.table("C:\\Users\\megacrazyleo\\Desktop\\SQL\\R\\bltper_1x1.txt", header=FALSE, skip
colnames(life_table) <- c("Year", "Age", "mx", "qx", "ax", "lx", "dx", "Lx", "Tx", "ex")

```

Import the life tables from mortality.org. We are going to import the dataset of Canada from 1921 - 2021.

```
year <- life_table$Year
age <- life_table$Age
qx <- life_table$qx
mx <- life_table$mx
ax <- life_table$ax
lx <- life_table$lx
dx <- life_table$dx
Lx <- life_table$Lx
Tx <- life_table$Tx
ex <- life_table$ex
px <- 1 - qx
```

Setting up variables

Year: Year or range of years (for both period & cohort data)

Age: Age group for n-year interval from exact age x to just before exact age x+n, where n=1, 4, 5, or infinity

m(x) Central death rate between ages x and x+n

q(x) Probability of death between ages x and x+n

a(x) Average length of survival between ages x and x+n for persons dying in the interval

l(x) Number of survivors at exact age x, assuming $l(0) = 100,000$

d(x) Number of deaths between ages x and x+n

L(x) Number of person-years lived between ages x and x+n

T(x) Number of person-years remaining after exact age x

e(x) Life expectancy at exact age x (in years)

Mortality Rates

```
# Setting up the plot
par(xpd = TRUE, mar = c(5, 4, 4, 6) + 0.1) # To ensure plot doesn't cover data

convert_age <- function(x) {
  x[x == "110+"] <- "110" # Age is character in our dataset, need to change to numeric
  suppressWarnings({
    as.numeric(x)
  })
}
age <- convert_age(age)
```

```

# Create a color palette
years <- unique(year)
color_palette <- colorRampPalette(c("blue", "green", "yellow", "red"))(length(years))

# Initialize plot
plot2 <- plot(NULL,
  xlim = range(age, na.rm = TRUE), # Exclude NAs from range calculation
  ylim = range(qx, na.rm = TRUE),  # Exclude NAs from range calculation
  main = "Mortality rates (Canada, Males & Females, 1921-2021)",
  xlab = "Age x",
  ylab = expression(paste("Mortality rate ", q[x])),
  type = "l"
)

# Plot each year's data
suppressWarnings({
  for (i in seq_along(years)) {
    year_data <- subset(life_table, Year == years[i])
    lines(year_data$Age, year_data$qx, col = color_palette[i], type = "l")
  }
})

# Colored legend
legend("topright", inset = c(-0.2,0),
  legend = c("1921", "1955", "1988", "2021"),
  col = color_palette[c(1, which.min(abs(years - 1955)),
    which.min(abs(years - 1988)), length(years))],
  lty = 1,
  title = "Year")

```

Mortality rates (Canada, Males & Females, 1921–2021)

We can see that mortality rates from recent years are much lower compared to the earliest years.

Life Expectancy

```
# Setting up the plot
par(xpd = TRUE, mar = c(5, 4, 4, 6) + 0.1) # To ensure plot doesn't cover data

# Create a color palette
years <- unique(year)
color_palette <- colorRampPalette(c("blue", "green", "yellow", "red"))(length(years))

plot3 <- suppressWarnings({
  plot(NULL,
    xlim = range(age, na.rm = TRUE), # Exclude NAs from range calculation
    ylim = range(ex, na.rm = TRUE),  # Exclude NAs from range calculation
    main = "Life Expectancy (Canada, Males & Females, 1921-2021)",
    xlab = "Age x",
    ylab = expression(paste("Life Expectancy ", e[x])),
    type = "l"
  )
})

# Plot each year's data
suppressWarnings({
```

```

for (i in seq_along(years)) {
  year_data <- subset(life_table, Year == years[i])
  lines(year_data$Age, year_data$ex, col = color_palette[i], type = "l")
}
})

# Colored legend
legend("topright", inset = c(-0.2, 0),
      legend = c("1921", "1955", "1988", "2021"),
      col = color_palette[c(1, which.min(abs(years - 1955)),
                             which.min(abs(years - 1988)), length(years))],
      lty = 1,
      title = "Year")

```

As we can see, the life expectancy is much higher from the years ~ 2021 as opposed to the years from ~1921 or even ~1955. Note for the early years, the life expectancy starts extremely low at age 0 and after a couple years, has a sharp increase. This can be explained mainly because it was much more difficult for an infant to survive the initial years. In later years, thanks to modern medicine, the survival rate of infants have risen much higher.

Let us focus on the year 2021.

2021 Life Table

```

life_table <- life_table[year == 2021, ] #Getting only data from the year 2021
year <- life_table$Year

```

```

age <- life_table$Age
qx <- life_table$qx
mx <- life_table$mx
ax <- life_table$ax
lx <- life_table$lx
dx <- life_table$dx
Lx <- life_table$Lx
Tx <- life_table$Tx
ex <- life_table$ex
px <- 1 - qx

life_table_2021 <- life_table[year == 2021, ] #Getting only data from the year 2021
year <- life_table_2021$Year

Retirement Plan

You're planning for your retirement at age 40. You want to buy an annuity that will provide you 10000 annually for life, starting at age 65. If you die before the annuity starts, you get paid nothing.

```
# Survival probabilities of (40)
```

```
kpx <- c(1, cumprod(px[(40 + 1):length(px)]))
```

```
# Discount factors (to age 40)
```

```
discount_factors <- (1 + 0.03) ^ -(0:(length(kpx) - 1))
```

```
# Pension benefits
```

```
benefits <- c(rep(0, 25), rep(10000, length(kpx) - 25))
```

```
# The single premium
```

```
single_premium <- sum(benefits * discount_factors * kpx)
single_premium
```

```
## [1] 38954.59
```

Suppose you want to finance this deferred life annuity with annual premiums payable for 25 years beginning at age 40. However, you plan to reduce your work hours from age 55 onwards, therefore the premium will reduce by 1 half after 15 years. What is the initial premium you will pay

```
# Premium pattern rho
```

```
rho <- c(rep(1, 15), rep(0.5, 10), rep(0, length(kpx) - 25))
```

```
# The initial premium
```

```
initial_premium <- single_premium / sum(rho * discount_factors * kpx, na.rm = TRUE)
initial_premium
```

```
## [1] 2763.3
```

```
# The annual premiums
```

```
annual_premiums <- initial_premium * rho
```

```
# Filter out the zero values from the annual premiums
```

```
filtered_annual_premiums <- annual_premiums[annual_premiums != 0]
```

```
# Sum of the annual premiums (no actuarial discounting)
```

```
sum(filtered_annual_premiums)
```

```
## [1] 55266
```

Find out if this product would be a favorable deal for you. How much would you receive if you died instead at 75, or 95?

```
# Curtate life expectancy of (40)
```

```
sum(kpx[-1])
```

```
## [1] 31.9023
```

```
# Present value of annuity benefits when (40) lives until age 75
```

```
subset1 <- 1:36
```

```
sum(benefits[subset1] * discount_factors[subset1])
```

```
## [1] 45516.78
```

```
# Present value of annuity benefits when (40) lives until age 95
```

```
subset2 <- 1:56

Life Insurance

You have bought a life insurance that is sold to 20 year olds and will pay 10000 at the end of the year of death if your death occurs at age 30. How much is the expected present value (EPV)

```

# 10-year survival probability of (20)
kpx <- prod(px[(20 + 1):(29 + 1)])
kpx

## [1] 0.9589195

# 10-year deferred mortality probability of (20)
kqx <- kpx * qx[30 + 1]
kqx

## [1] 0.0009397411

# Discount factor
discount_factor <- (1 + 0.01) ^ - 11
discount_factor

## [1] 0.8963237

# EPV of the simple life insurance
10000 * discount_factor * kqx

## [1] 8.423123

```

Whole, Temporary and Deferred Life Insurance

Function to find EPV of a whole life Insurance

```

# Define the whole life insurance function
whole_life_insurance <- function(age, i, life_table_2021) {
  qx <- life_table_2021$qx
  px <- 1 - qx
  kpx <- c(1, cumprod(px[(age + 1):(length(px) - 1)]))
  kqx <- kpx * qx[(age + 1):length(qx)]
  discount_factors <- (1 + i) ^ - (1:length(kqx))
  sum(discount_factors * kqx, na.rm = TRUE)
}

# Function to plot EPV by age
plot_by_age <- function(life_table_2021, interest_rate = 0.03) {
  ages <- 0:(length(life_table_2021$qx) - 1)
  epvs <- sapply(ages, function(age) whole_life_insurance(age, interest_rate, life_table_2021))
  plot(ages, epvs, type = "l", col = "blue",
       main = "EPV of Whole Life Insurance by Age",
       xlab = "Age", ylab = "EPV", lwd = 2)
}

# Function to plot EPV by interest rate for a given age
plot_by_interest_rate <- function(life_table_2021, target_age = 20) {
  interest_rates <- seq(0.01, 0.1, by = 0.01)
  epvs <- sapply(interest_rates, function(i) whole_life_insurance(target_age, i, life_table_2021))
  plot(interest_rates, epvs, type = "l", col = "red",
       main = paste("EPV of Whole Life Insurance for Age", target_age, "by Interest Rate"),
       xlab = "Interest Rate", ylab = "EPV", lwd = 2)
}

# Plot the EPV by age
plot_by_age(life_table_2021, interest_rate = 0.03)

```

EPV of Whole Life Insurance by Age

```
# Plot the EPV by interest rate for age 20  
plot_by_interest_rate(life_table_2021, target_age = 20)
```

EPV of Whole Life Insurance for Age 20 by Interest Rate

Temporary Life Insurance

```
# EPV of a whole life insurance for (20) at interest rate 2% using life_table
whole_life_insurance(20, 0.02, life_table_2021)
```

Finding the EPV of a life insurance where the coverage is restricted in time for a 20 year old in Canada in 2021 using an interest rate of 2%

```
## [1] 0.301949
```

```
# Function to compute the EPV of a temporary life insurance
temporary_life_insurance <- function(age, n, i, life_table_2021) {
  qx <- life_table_2021$qx
  px <- 1 - qx
  kpx <- c(1, cumprod(px[(age + 1):(age + n - 1)]))
  kqx <- kpx * qx[(age + 1):(age + n)]
  discount_factors <- (1 + i) ^ - (1:length(kqx))
  sum(discount_factors * kqx)
}
```

```
# EPV of a temporary life insurance for (20) over a period of 45 years at interest rate 2% using life_table
temporary_life_insurance(20, 45, 0.02, life_table_2021)
```

```
## [1] 0.059754
```

```
# EPV of a whole life insurance for (20) at interest rate 2% using life_table
whole_life_insurance(20, 0.02, life_table_2021)
```

```
## [1] 0.301949
```

Deferred Life Insurance

```
# Function to compute the EPV of a deferred whole life insurance
deferred_life_insurance <- function(age, u, i, life_table_2021) {
  qx <- life_table_2021$qx; px <- 1 - qx
  kpx <- c(1, cumprod(px[(age + 1):(length(px) - 1)]))
  kqx <- kpx * qx[(age + 1):length(qx)]
  discount_factors <- (1 + i) ^ - (1:length(kqx))
  benefits <- c(rep(0, u), rep(1, length(kpx) - u))
  sum(benefits * discount_factors * kqx)
}
```

```
# EPV of a deferred life insurance for (20) deferred over 45 years at interest rate 2% using life_table_2021
deferred_life_insurance(20, 45, 0.02, life_table_2021)
```

Calculating EPV of a deferred life insurance for constant interest rate on age x

```
## [1] 0.242195
```

```
# Deferred mortality probabilities of (48)
kqx <- c(1, cumprod(px[(48 + 1):(73 + 1)])) * qx[(48 + 1):(74 + 1)]
i <- 0.05

# Discount factors
discount_factors <- (1 + i) ^ - (1:length(kqx))

# Death benefits
benefits <- c(rep(0, 7), rep(40000, length(kqx) - 7))

# EPV of the death benefits
EPV_death_benefits <- sum(benefits * discount_factors * kqx)
EPV_death_benefits
```

Suppose you are age 48 and want to insure a benefit of 40000 for death between the ages of 55 and 75. Assume interest rate is 5%

```
## [1] 2377.926
```

```
# Pure endowment
EPV_pure_endowment <- 80000 * (1 + i) ^ - 27 * prod(px[(48 + 1):(74 + 1)])
EPV_pure_endowment
```

Now suppose you want to add a savings component to the policy that will add 80000 if you are alive at age 75. You want to finance this endowment insurance with constant premiums.

```
## [1] 10614
```

```
# Premium pattern
kpx <- c(1, cumprod(px[(48 + 1):(73 + 1)]))
discount_factors <- (1 + i) ^ - (0:(length(kpx) - 1))
rho <- rep(1, length(kpx))
```

```

EPV_rho <- sum(rho * discount_factors * kpx)
EPV_rho

## [1] 13.33744

# Premium level
(EPV_death_benefits + EPV_pure_endowment) / EPV_rho

## [1] 974.0947

```
